CONTENTS 1

The dataset's features describe characteristics of the cell nuclei on the image. The features information are specified below:

- Attribute Information:
 - 1. ID number
 - 2. Diagnosis (M = Malignant, B = Benign)
- Ten features were computed for each cell nucleus:
- 1. radius: mean of distances from center to points on the perimeter
- 2. texture: standard deviation of grey-scale values
- 3. perimeter
- 4. area: Number of pixels inside contour $+\frac{1}{2}$ for pixels on perimeter
- 5. smoothness: local variation in radius lengths), , t
- 6. compactness: perimeter 2 / area 1.0; this dimensionless number is at a minimum with a circular disk and increases with the irregularity of the boundary, but this measure also increases for elongated cell nuclei, which is not indicative of malignancy
- 7. concavity: severity of concave portions of the contour
- 8. concave points: number of concave portions of the contour
- 9. symmetry
- 10. fractal dimension: "coastline approximation" 1; a higher value corresponds a less regular contour and thus to a higher probability of malignancy

The mean, standard error and "worst" or largest (mean of the three largest values) of these features were computed for each image, resulting in 30 variables. From this diagnosis, 714 of the cases were classified as benign tumors and 424 were considered malignant tumors. All cancers and some of the benign masses were histologically confirmed

The column 33 is invalid.

```
# View quantity of each value in the diagnosis variable table(data$diagnosis)
```

```
B M
714 424
```

```
# Convert from char to factor for diagnosis variable
data$diagnosis <- as.factor(data$diagnosis)
# the 33 column is invalid
data[,33] <- NULL</pre>
```

Chapter 1

Methods and Analysis

1.1 Data Analysis

By observing the dataset, we found that it contains 1138 observations with 32 variables.

```
str(data)
```

```
'data.frame': 1138 obs. of 32 variables:

Max.	:1.2520	Max.	:0.29100	Max.	:0.6638	Max.	:0.20750

We have to check if the dataset has any missing value:

\$id

[1] 0

\$diagnosis

[1] 0

\$radius_mean

[1] 0

\$texture_mean

[1] 0

\$perimeter_mean

[1] 0

\$area_mean

[1] 0

 ${\tt \$smoothness_mean}$

[1] 0

\$compactness_mean

[1] 0

\$concavity_mean

Γ1] (

\$concave.points_mean

[1] 0

\$symmetry_mean

[1] 0

 ${\tt \$fractal_dimension_mean}$

[1] 0

\$radius_se

[1] 0

\$texture_se

[1] 0

\$perimeter_se

[1] 0

\$area_se

[1] 0 \$smoothness_se [1] 0 \$compactness_se [1] 0 \$concavity_se [1] 0 \$concave.points_se [1] 0 \$symmetry_se [1] 0 \$fractal_dimension_se [1] 0 \$radius_worst [1] 0 \$texture_worst [1] 0 \$perimeter_worst [1] 0 \$area_worst [1] 0 \$smoothness_worst [1] 0 \$compactness_worst [1] 0 \$concavity_worst [1] 0

\$concave.points_worst
[1] 0

\$symmetry_worst
[1] 0

\$fractal_dimension_worst

[1] 0

It results that there aren't NA values. By analyzing the the dataset we discover that it is a bit unbalanced in its proportions:

1.1. DATA ANALYSIS 7

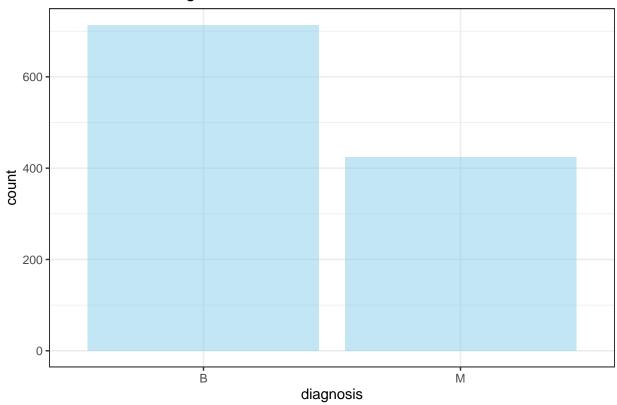

```
prop.table(table(data$diagnosis))
```

```
B M
0.6274165 0.3725835
```

Also the plot of proportions confirms that the target variable is slightly unbalanced.

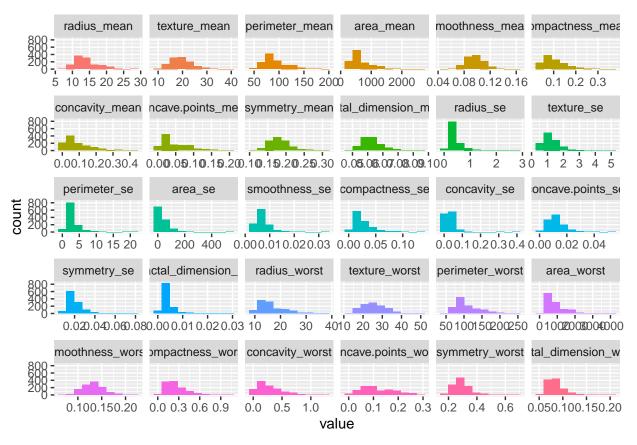

```
options(repr.plot.width=4, repr.plot.height=4)
ggplot(data, aes(x=diagnosis)) +
  geom_bar(fill="sky blue",alpha=0.5) +
  theme_bw() +
  labs(title="Distribution of Diagnosis")
```

Distribution of Diagnosis

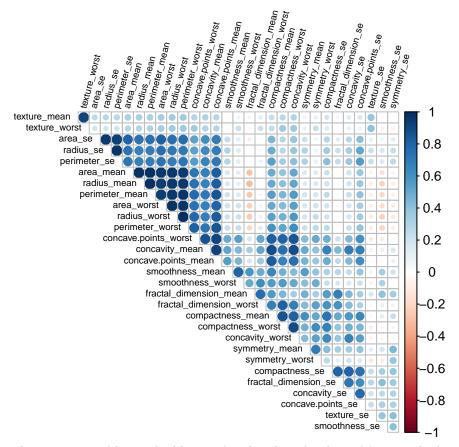

The most variables of the dataset are normally distributed as show with the below plot:

```
plot_num(data %>% select(-id), bins=10)
```

Now we have to check if the is any correlation between variables as machine learning algorithms assume that the predictor variables are independent from each others.

1.1. DATA ANALYSIS 9

As shown by this plot, many variables are highly correlated with each others. Many methods perform better if highly correlated attributes are removed. The Caret R package provides the findCorrelation which will analyze a correlation matrix of your data's attributes report on attributes that can be removed. Because of many correlations may cause some of machine learning models fail.

```
# find attributes that are highly corrected (ideally >0.90)
highlyCorrelated <- findCorrelation(correlationMatrix, cutoff=0.9)
# print indexes of highly correlated attributes
print(highlyCorrelated)</pre>
```

[1] 7 8 23 21 3 24 1 13 14 2

Selecting the right features in our data can mean the difference between mediocre performance with long training times and great performance with short training times.

```
# Remove correlated variables
data2 <- data %>%select(-highlyCorrelated)
# number of columns after removing correlated variables
ncol(data2)
```

[1] 22

The new dataset has been removed 10 variables, it's 22 variables now.

1.2 Modelling Approach

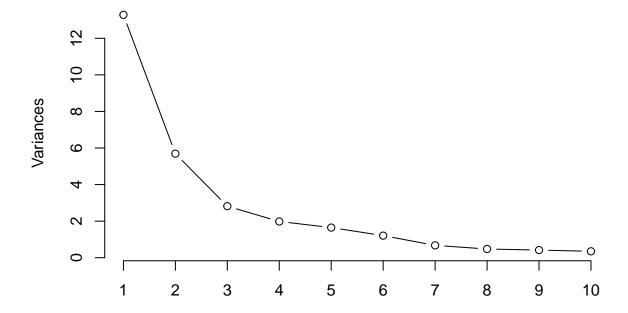

1.2.1 Modelling

Principal Component Analysis (PCA).

To avoid redundancy and relevancy, we used the function 'prcomp' to calculate the Principal Component Analysis (PCA) and select the rights components to avoid correlated variables that can be detrimental to our clustering analysis. One of the common problems in analysis of complex data comes from a large number of variables, which requires a large amount of memory and computation power. This is where PCA comes in. It is a technique to reduce the dimension of the feature space by feature extraction. The main idea of PCA is to reduce the dimension of a data set consisting of many variables correlated with each other, either heavily or lightly, while retaining the variation present in the dataset, up to the maximum extent. The same is done by transforming the variables to a new set of variables, which are known as the principal components (or simply, the PCs) and are orthogonal, ordered such that the retention of variation present in the original variables decrease as we move down in the order.

```
pca_res_data <- prcomp(data[,3:ncol(data)], center = TRUE, scale = TRUE)
plot(pca_res_data, type="1")</pre>
```

```
summary(pca_res_data)
```

```
Importance of components:
```

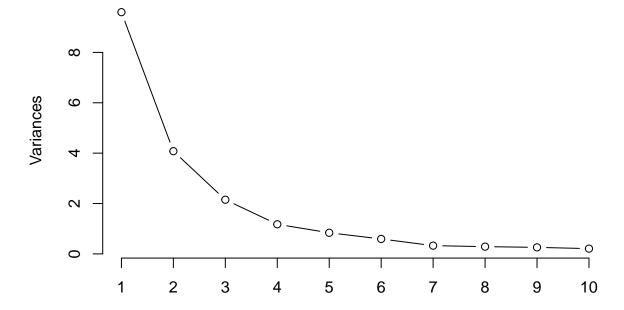

```
PC1 PC2 PC3 PC4 PC5 PC6 PC7 Standard deviation 3.6444 2.3857 1.67867 1.40735 1.28403 1.09880 0.82172
```

```

```

The above table shows that 95% of the variance is explained with 8 PC's in the transformed dataset data2.

```
pca_df <- as.data.frame(pca_res_data2$x)
ggplot(pca_df, aes(x=PC1, y=PC2, col=data$diagnosis)) + geom_point(alpha=0.5)</pre>
```

The data of the first 2 components can be easily separated into two classes. This is caused by the fact that the variance explained by these components is not large. The data can be easily separated.

```
g_pc1 <- ggplot(pca_df, aes(x=PC1, fill=data$diagnosis)) + geom_density(alpha=0.25)
g_pc2 <- ggplot(pca_df, aes(x=PC2, fill=data$diagnosis)) + geom_density(alpha=0.25)
grid.arrange(g_pc1, g_pc2, ncol=2)</pre>
```

Linear Discriminant Analysis (LDA)

Another approach is to use the Linear Discriminant Analysis (LDA) instead of PCA. LDA takes in consideration the different classes and could get better results. The particularity of LDA is that it models the distribution of predictors separately in each of the response classes, and then it uses Bayes' theorem to estimate the probability. It is important to know that LDA assumes a normal distribution for each class, a class-specific mean, and a common variance.

```
lda_res_data <- MASS::lda(diagnosis~., data = data, center = TRUE, scale = TRUE)
lda_res_data</pre>
```

```
Call:
```

```
lda(diagnosis ~ ., data = data, center = TRUE, scale = TRUE)
```

1.2.2 Model creation

We are going to get a training and a testing set to use when building some models. We split the modified dataset into Train (80%) and Test (20%), in order to predict whether it is a cancer cell is Benign or Malignant, by building machine learning classification models.

```
number = 15,
#Either the number of folds or number of resampling iterations
classProbs = TRUE,
summaryFunction = twoClassSummary)
```

1.2.3 Naive Bayes Model

The Naive Bayesian classifier is based on Bayes' theorem with the independence assumptions between predictors. A Naive Bayesian model is easy to build, with no complicated iterative parameter estimation which makes it particularly useful for very large datasets. Bayes theorem provides a way of calculating the posterior probability, P(c|x), from P(c), P(x), and P(x|c). Naive Bayes classifier assume that the effect of the value of a predictor (x) on a given class (c) is independent of the values of other predictors. This assumption is called class conditional independence.

Confusion Matrix and Statistics

```

Neg Pred Value : 0.9424
Prevalence : 0.3717
Detection Rate : 0.3863
Detection Prevalence : 0.3850

Balanced Accuracy: 0.9136

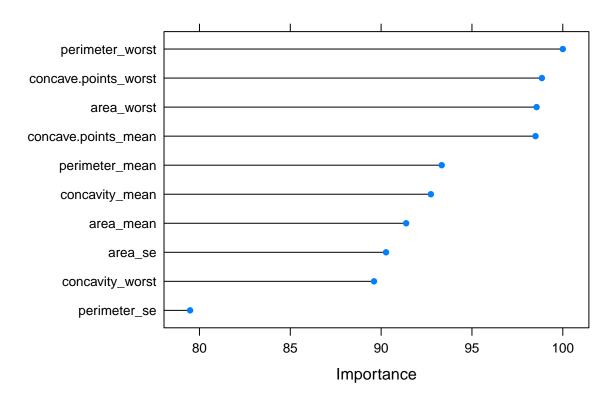

'Positive' Class : M

We can note the accuracy with such model. We will later describe better these metrics, where: Sensitivity (recall) represent the true positive rate: the proportions of actual positives correctly identified. Specificity is the true negative rate: the proportion of actual negatives correctly identified. Accuracy is the general score of the classifier model performance as it is the ratio of how many samples are correctly classified to all samples. F1 score: the harmonic mean of precision and sensitivity. Accuracy and F1 score would be used to compare the result with the benchmark model. Precision: the number of correct positive results divided by the number of all positive results returned by the classifier.

The most important variables that permit the best prediction and contribute the most to the model are the following:

```
plot(varImp(model_naiveb), top=10, main="Top variables - Naive Bayes")
```

Top variables - Naive Bayes

1.2.4 Logistic Regression Model

Logistic Regression is widely used for binary classification like (0,1). The binary logistic model is used to estimate the probability of a binary response based on one or more predictor (or independent) variables (features).

1.2.5 Random Forest Model

Random forests are a very popular machine learning approach that addresses the shortcomings of decision trees using a clever idea. The goal is to improve prediction performance and reduce instability by averaging multiple decision trees (a forest of trees constructed with randomness). Random forest is another ensemble method based on decision trees. It split data into sub-samples, trains decision tree classifiers on each sub-sample and averages prediction of each classifier. Splitting dataset causes higher bias but it is compensated by large decrease in variance. Random Forest is a supervised learning algorithm and it is flexible, easy to use machine learning algorithm that produces, even without hyper-parameter tuning, a great result most of the time. It is also one of the most used algorithms, because of it's simplicity and the fact that it can be used for both classification and regression tasks. Random forest builds multiple decision trees and merges them together to get a more accurate and stable prediction.

1.2.6 K Nearest Neighbor (KNN) Model

KNN (K-Nearest Neighbors) is one of many (supervised learning) algorithms used in data mining and machine learning, it's a classifier algorithm where the learning is based "how similar" is a data from other. K nearest neighbors is a simple algorithm that stores all available cases and classifies new cases based on a similarity measure (e.g., distance functions).

The most important variables that permit the best prediction and contribute the most to the model are the following:

1.2.7 Neural Network with PCA Model

Artificial Neural Networks (NN) are a types of mathematical algorithms originating in the simulation of networks of biological neurons. An artificial Neural Network consists of nodes (called neurons) and edges (called synapses). Input data is transmitted through the weighted synapses to the neurons where calculations are processed and then either sent to further neurons or represent the output.

Neural Networks take in the weights of connections between neurons . The weights are balanced, learning data point in the wake of learning data point. When all weights are trained, the neural network can be utilized to predict the class or a quantity, if there should arise an occurrence of regression of a new input data point. With Neural networks, extremely complex models can be trained and they can be utilized as a kind of black box, without playing out an unpredictable complex feature engineering before training the model. Joined with the "deep approach" even more unpredictable models can be picked up to realize new possibilities.

The most important variables that permit the best prediction and contribute the most to the model are the following:

```
plot(varImp(model_nnet_pca), top=8, main="Top variables - NNET PCA")
```

1.2.8 Neural Network with LDA Model

We are going to create a training and test set of LDA data created in previous chapters:

```
train_data_lda <- lda_df_predict[data_sampling_index, ]
test_data_lda <- lda_df_predict[-data_sampling_index, ]</pre>
```

As we can observe from the following plot, four models, Naive_Bayes, KNN, Logistic_regr, and Neural_LDA have great variability, depending of the processed sample :

```
bwplot(models_results, metric="ROC")
```

The Neural Network LDA model achieve a great auc (Area Under the ROC Curve) with some variability. The ROC (Receiver Operating characteristic Curve is a graph showing the performance of a classification model at all classification thresholds) metric measure the auc of the roc curve of each model. This metric is independent of any threshold. Let's remember how these models result with the testing dataset. Prediction classes are obtained by default with a threshold of 0.5 which could not be the best with an unbalanced dataset like this.

```
confusionmatrix_list <- list(
   Naive_Bayes=confusionmatrix_naiveb,
   Logistic_regr=confusionmatrix_logreg,
   Random_Forest=confusionmatrix_randomforest,
   KNN=confusionmatrix_knn,</pre>
```

```
Neural_PCA=confusionmatrix_nnet_pca,
   Neural_LDA=confusionmatrix_nnet_lda)
confusionmatrix_list_results <- sapply(confusionmatrix_list, function(x) x$byClass)
confusionmatrix_list_results %>% knitr::kable()
```

Chapter 3

Discussion

We will now describe the metrics that we will compare in this section.

Accuracy is our starting point. It is the number of correct predictions made divided by the total number of predictions made, multiplied by 100 to turn it into a percentage.

Precision is the number of True Positives divided by the number of True Positives and False Positives. Put another way, it is the number of positive predictions divided by the total number of positive class values predicted. It is also called the Positive Predictive Value (PPV). A low precision can also indicate a large number of False Positives.

Recall (Sensitivity) is the number of True Positives divided by the number of True Positives and the number of False Negatives. Put another way it is the number of positive predictions divided by the number of positive class values in the test data. It is also called Sensitivity or the True Positive Rate. Recall can be thought of as a measure of a classifiers completeness. A low recall indicates many False Negatives.

The F1 Score is the 2 x ((precision x recall) / (precision + recall)). It is also called the F Score or the F Measure. Put another way, the F1 score conveys the balance between the precision and the recall.

The best results for sensitivity (detection of breast cancer malign cases) is Neural Network with PCA model which also has a great F1 score.

```
metric
                           best_model

Chapter 4

Conclusion

This research treats the Breast Cancer diagnosis problem as a pattern classification problem. In this report we investigated several machine learning model and we selected the optimal model by selecting a high accuracy level combined with a low rate of false-negatives (the means that the metric is high sensitivity).

The Neural Network with PCA model had the optimal results for F1 (0.9879518), Sensitivity (0.9761905) and Balanced Accuracy (0.9880952)
